ALLUVIAL FILLS NEAR GALLUP, NEW MEXICO

By LUNA B. LEOPOLD and C. T. SNYDER

ABSTRACT

Valleys near Gallup, N. Mex., similar to many in the Southwest, were filled in recent times with alluvium. This material is now being eroded by systems of gullies, and the walls of these gullies provide exposures by which the history of deposition of the alluvium can be traced.

Alluvial fills near Gallup have been eroded at least twice previously within recent time. The middle fill of the three that are recognizable contains pots- teads of Pueblo II age, indicating that deposition was occurring as late as A.D. 1200.

The chronology of alluviation and degradation for valleys in the Gallup area appears to agree with that for other valleys in the Southwest which have been studied.

INTRODUCTION

Geologic studies in the Southwest during the past two decades have furnished detailed knowledge of the late Pleistocene and Recent history of widely separated areas. Through the work of geologists and archaeologists, a working hypothesis concerning the sequences of erosion and sedimentation and their probable relation to climate and early man is available. This report discusses a locality where such relations have been worked out.

Part of the Water Resources Division's program for the investigation of sediment problems in the United States, the report was prepared in the Technical Coordination Branch under the general supervision of R. W. Davenport, Chief. The manuscript was read by the late Professor Kirk Bryan, of Harvard University, whose comments are gratefully acknowledged.

GENERAL DESCRIPTION OF THE GALLUP AREA

LOCATION AND DRAINAGE

The area to be discussed includes the reach of the Puerco River (Rio Puerco del Oeste) at Gallup, in northwestern New Mexico, and certain
ephemeral streams tributary to the Chaco River that drain the south end of the Chuska Mountains (fig. 1). These ephemeral streams are within the Mexican Springs Experiment Station, formerly under the jurisdiction of the U. S. Soil Conservation Service and now under the Bureau of Indian Affairs. The station is 18 miles north of Gallup on U. S. Highway 666.

![Map of the region](image)

Figure 1.—Map showing the location of the Gallup area, N. Mex.

The Puerco River rises in the Jurassic and Cretaceous sandstone and shales between the south face of the Dalton Plateau and the north edge of the Zuni Mountains; it flows westward through the town of Gallup toward the Little Colorado River. The streams in the Mexican Springs area head in the Eocene (?) Chuska sandstone and Tohato shale and flow eastward over extensive areas underlain by the Upper Cretaceous Mesaverde formation to join the Chaco River, a tributary of the San Juan.
**GEOLOGIC HISTORY**

The late Tertiary and early Quaternary history of the area has been discussed by Reich (1941). He mapped a series of eight graded erosion surfaces, generally gravel-capped, representing periods of temporary stability during the lowering of the local base level of Mexican Springs Wash and its predecessors. The erosion surfaces and during these temporary halts are at successively lower altitudes and are considered by Reich to be stages during the Canyon erosion cycle (Pleistocene) as defined at the Grand Canyon (Fenneman, 1931).

The Canyon erosion cycle was followed by the alluviation of the canyons. This process, which began while glaciers presumably still existed in the southern Rocky Mountains, was interrupted several times by erosion. The details of these alternating periods of erosion and deposition are the subject of the present discussion. Reich, however, did not attempt to study these relatively recent episodes. He merely observes (1941, p. 56): "The alluvium in the valley bottoms is a recent flood plain deposit with a thickness of thirty feet. It consists of silty clays and abundant if not predominant sandy members." He mentions, also, that "no single episode in the Quaternary history of the Mexican Springs district seems so characterized by wind action as the period between the No. 1 and No. 2 valley fills [Jeddito and Tsegi formations] described by Hack 1939; but see also 1942] for the Jeddito [Jadito] Valley, 90 miles west."

During the past century the present arroyos have cut into the alluvium and have exposed evidences of the previous periods of cutting and deposition on the gully walls, not only in the area described by Reich, but also along the Puerco River near Gallup.

**STRATIGRAPHY OF THE ALLUVIUM**

The alluvium that fills the original valleys cut in the relatively soft shale and sandstone bedrock varies greatly in depth. At a point just above Gallup, the original valley of the Puerco River was cut to a level only 20 feet lower than the top of the alluvium, but springs at the new overpass on U. S. Highway 66, nine miles west of Gallup, have shown that bedrock lies 95 feet below the top of the alluvium at that locality.

This valley fill consists of bodies of alluvium separated by marked unconformities. The older alluvial fill is here called the Gamerco formation; it rests unconformably on bedrock and consists of sand and silt grading rapidly downward to gravel. On the eroded surface
of the Gamerco a distinct soil profile characterized by a zone of high caliche accumulation (B horizon) was observed. Just east of Gallup, this surface lies about 15 feet below the top of the later alluvium.

After a period of strong erosion, a body of water-laid sand and loess containing lenses of fine gravel, here called the Nakibito formation, was deposited on the eroded surface of the Gamerco. Potsherds of Pueblo I and Pueblo II types are found in this alluvium, which filled the Puerco River valley to the level of its present floor. A period of moderate to weak erosion followed, and in some localities long channels about 150 feet wide were cut. Ordinarily these channels were about 9 feet deep, but in places they reached a depth of 18 feet. They were probably discontinuous in many places but were nevertheless of appreciable size, and in them a third fill was deposited. In other localities examined, no erosion of consequence followed the deposit of the Nakibito until, in modern times, the present arroyos were formed. Dune formation is now in progress, although most of these dunes are stabilized by vegetation.

Bryan (1925) showed that the year 1885 marked the general beginning of arroyo cutting in the Southwest, but he indicated that in northern Arizona and southern Colorado the date is apparently earlier, perhaps soon after 1860. This agrees in general with the notes of Beale (1858), who in 1857 observed that the Rio "Puercó" (Puerco) 2 days' journey by wagon west of Navajo Church near Gallup, was "a deep gulley." However, where the Puerco joins the Little Colorado, Beale found large cottonwoods in the river bottom—which would indicate no appreciable erosion at that place—even though he had just cut down the banks of two arroyos "to admit passage of our wagon.

The modern arroyo, like many in the Southwest, probably began as a series of short discontinuous gullies. Figure 2 shows that the Puerco River above Gallup was about 6 feet deep in 1901 and suggests that a greater part of the erosion forming the present arroyo occurred in the period 1901-46 than in the 40 years prior to 1901.
Figure 2.—The Puerco River channel 2 miles east of Gallup, N. Mex., showing the progress of erosion in 45 years. The upper photograph was taken by N. H. Burton (U.S. no. 874) in 1901; the lower by L. B. Leopold in August 1946. The gully in 1901 was about 6 feet deep; in 1946 it was 20 feet deep, and its walls were nearly vertical. Note that the road cut (A) in the 1901 view was filled with soil material when the railroad grade was moved; the old road now appears as light-colored fill (A) in the gully wall just left of the center of the lower picture. The large rocks near which the man is standing in the lower photograph appear in the lower left of the upper photograph, showing the increase in the width of the gully.
THE GANARO FORMATION

The Gamarco formation (fig. 3) receives its name from a suburb of Gallup. At the type locality near the outskirts of the town, 300 yards east of the El Rancho Hotel, the Gamarco crops out in the gulch wall of the Puerco River. It appears near the bed of the present stream as an eroded remnant of fossil soil, the complete profile of which can be seen in only a few places. The formation occurs along the arroyo tributary to the Puerco River where that tributary is bridged, 1 1/2 miles east of Gallup, by the railroad and by Highway 66 (fig. 4). It is exposed in the walls of Mexican Springs Wash 18 miles north of Gallup and 4,000 feet west of Highway 66, which crosses the wash on a bridge, and it crops out in Deer Springs Wash, Black Creek Wash, and Chuska Wash, all in the general vicinity of Mexican Springs.
The stratigraphic sequence of the Gamerco formation at its type locality is as follows:

**Stratigraphic sequence of Gamerco formation at type locality near El Rancho Hotel, Gallup, N. Mex.**

Stratigraphic sequence of Gamercro formation at type locality near El Rancho Hotel, Gallup, N. Mex.—Continued

Gamercro formation—Continued

Sand, brown, compact, silty, fine, with white mottling of caliche. Small veins of caliche extend downward nearly to base of section; top 12 inches is particularly hard and forms cliffs; whole compact layer is fluted and abraded by flow of present stream. Nodules and veins of caliche stand out in relief from water-worn surfaces (fig. 3)...

Gravel, fine, partly cemented with caliche, containing sub-rounded pebbles of different types of rocks characterizing area; many pebbles covered with strong layer of caliche (fig. 5)...

Disconformity.

Bedrock: Shale and sandstone of Gibson coal member of Mesa Verde formation (Upper Cretaceous), comprising floor of present stream channel at this point.

---

Figure 5.—Contact between the Mesaverde formation (Upper Cretaceous) below and Gamercro formation above in Mexican Springs Wash, 4,000 feet upstream from Highway 966 and 18 miles north of Gallup, N. Mex. This is a good exposure of the Game in that it shows the caliche-coated basal gravel overlain by the compact, cliff-forming horizon of the fossil soil. The compactness results from the high content of caliche cementing the grains. The A horizon of the fossil soil is missing. The slopes of the vertical wall are composed of material of the Nakahito formation, whose surface is hummocky with small stabilized dunes.
The calichified horizon containing concretions is considered to be
the B horizon of a fossil soil. The material of this layer, when
observed under a lens, is seen to be perforated with large numbers of
minute, irregular holes and tubes, mostly lined with calcite, aragonite,
amorphous caliche. These minute tubes appear to have been
formed by the decomposition of enclosed rootlets. No bones nor
artifacts have yet been found in this formation.
Practically every exposure of the Gamerco formation occurs where
shock, the Mesaverde formation, crops out in the gully channel.
It appears that the few remnants of the Gamerco are preserved only
here the bedrock locally prevented further deepening of the channel
inhibited complete erosion by lateral corrosion.

NAKAIBITO FORMATION

GENERAL FEATURES AT TYPE LOCALITY

Most of the alluvium in the valleys near Gallup varies greatly in
detail from one wash to another, depending primarily on the rocks
from which the sand, silt, and clay were derived. Mexican Springs
wash near Nakaibito, 18 miles north of Gallup, is chosen as the type
locality of the Nakaibito formation because the formation contained
potsherds there. "Nakaibito" is the Navajo word for Mexican
Springs and is the local name for the immediate vicinity of the experi-
ment station headquarter buildings.
The exposure at the type locality is shown on the map and the dia-
grammatic cross section of figure 6. The older Gamerco formation
also is exposed, and the eroded surface on which the Nakaibito was
placed down is easily seen. The Nakaibito here consists of 22 feet of
interbedded tan-brown sand and silt, including several thick layers
of unconsolidated yet massive sand. The fill is irregularly cross-bedded
and contains occasional lenses of unconsolidated, subrounded fine
gravel, particularly near the base. Bits of coal from the nearby Gibson
member of the Mesaverde formation are abundant.

Near Gallup, the fill that overlies the Gamerco formation and pre-
sumably is equivalent to the Nakaibito consists of 20 feet of sandy silt
layers 1 to 3 feet thick. It is cross-bedded in places and contains
occasional lenses of fine gravel. Darker bands representing partial
development occur, particularly near the top of the fill.

Two potsherds were buried 14 feet from the present top of the
exposure at the type locality, as shown in the cross section of figure 6.
They lay in place within a horizontal distance of 50 feet and a vertical
distance of only 1 foot. One sherd, of late Pueblo I utility ware, in-
cluded part of a handle. The second sherd was Chaco black-on-white
ware of Pueblo II age. Both were identified and dated by Dr. Dorothy
Huhrs, of the Hancock Foundation, whose assistance is gratefully
acknowledged.
On the bedrock hill adjacent to the type locality of the Nakabito formation, potsherds were common, lying on the surface of the recent wind-worked colluvium. Identified by Dr. Luhrs, they included fragments of Exuberant-corrugated ware of Pueblo I age, Kiutuhla of Pueblo II age, and Chaco black-on-white of Pueblo II age. These sherds probably indicate that the locality was a camp site, occupied occasionally over a period of time.

Because of the adjacent camp site, it may be logically assumed that sherds of various ages were washed by floods from some similar camp site farther upstream during the deposition of the Nakabito formation.
The sherds in place in the fill indicate that alluviation was in progress at the type locality during or after Pueblo II time, or A. D. 900-1100.

**DIFFERENTIATION WITHIN THE FORMATION**

Though in most places there are no indications of discontinuities within the Nakaibito formation, two localities offer evidence of a possible pause during deposition. Exposed in the walls of Deer Springs Wash, 1 mile above the diversion dam and 2 miles southeast of the Mexican Springs Experiment Station headquarters, is an eroded mass of older material, buried by the main portion of the Nakaibito formation. No lithologic evidence of any age difference between this buried, eroded mass of alluvium and the main body of the fill was observable other than the markedly disconformable contact. The buried mass consists of layers of yellowish-buff sand and silt, whereas the overlying material consists of thin layers of yellowish-buff clay and sand. The contact, which slopes 19° to 27° in the exposed section, is marked by a thin layer of clay containing gray clay masses which break open to show radial cracks stained with limonite.

The stratigraphic relations are shown diagrammatically in section 6 of figure 7. As is indicated, an outcrop of heavily calcified fossil wood of the Gamerco formation occurs nearby, and the buried sand outcrop of the older phase of the Nakaibito contains no caliche. The sand outcrop therefore is probably much younger than the Gamerco formation.

A second indication of a possible pause during the deposition of the Nakaibito occurs in the wall of Mexican Springs Wash about a quarter of a mile above the mouth of Chuska Wash. It is shown in the following section:

**Stratigraphic section in Mexican Springs Wash, one-quarter mile above mouth of Chuska Wash**

</table>

The caliche in this section was not nearly so well developed as that of the Gamerco formation, and the absence of concretions, which have
been found in every outcrop of the Gamerco, definitely shows that the alluvium just described is younger than the Gamerco. The moderately well developed soil at the present ground surface of the section indicates greater stability of the upper surface here than over the wide areas of the Nakaibito occurring at lower altitudes, where soil development at the present surface is mostly absent.

The foregoing evidence indicates that the Nakaibito formation is two phases, the older of which is separated by erosion from the younger. This division, as will be shown, also is characteristic of Hack's (1942) Tsogi formation in the Hopi area and Albritton and Bryan's (1939) Calamity formation in trans-Pecos Texas.

**POST-NAKAIBITO EROSION AND CHANNELING**

Channels of moderate size were cut and wholly or partly filled after the deposition of the Nakaibito formation was essentially complete. In the 2-mile reach upstream from Gallup, a filled chan
in the Nakabito is well exposed and easy to trace. Just east of
up it consists of a cut 9 to 13 feet deep and 150 feet wide, filled
in thin bands of red sandy clay and reddish-brown sandy silt.
Banks are somewhat rounded, and the cross section has the form
flat U (fig. 8). At one exposure a remnant of a bank 4 feet high
still preserved because the channel at that point was not com-
pletely filled. (See sec. B of fig. 7.) A short distance upstream,

However, the red material filled the channel to the top and actually
was deposited as a layer nearly a foot thick over a broad zone adjacent
in the filled channel.

Three miles east of Gallup, at the hogback formed by steeply
tipping beds of the Cretaceous Dakota sandstone, the filled channel
in the Nakabito formation was as deep as the present arroyo (20
feet), and its floor actually reached bedrock, which also constitutes
the floor of the present arroyo there. The filled channel is more
than 120 feet wide at this point, and its sides slope 60°. The lowest 10 feet is filled with thick layers of coarse reddish sand and a few thin layers of red silt. The upper 10 feet consists of thinly interbedded red clay and lenses of reddish sand. (See sec. C of fig. 7.) The difference in color between the filled channel and the adjacent old alluvium is striking.

Upstream from the hogback, a large part of the alluvium is red and the buried channel was not traced in detail. Downstream from Gallup, the Puerco River channel becomes very shallow and its banks are no more than 4 feet in height. No evidence of fill channeling was observed. The fact that the main body of the fill loses its redness downstream indicates that the alluvium from the lower tributaries masked the red material contributed by headwater tributaries. The old channel extended upstream in a continuous gully far enough to tap the predominantly red material with which it was filled. The disappearance of the red color downstream was not due to gradual shallowing of the buried channel, at least in the reach where exposures are found, although possibly this channel was discontinuous and shallowed downstream below the reach where its outcrops could be mapped.

At the type locality of the Nakaibito on Mexican Springs Wash, a filled channel, the bottom of which is only 3 feet above the present arroyo floor, is exposed. The top of the filled channel occurs at the level of an old meander scar, as can be seen in figure 6. Numerous small tributaries in the vicinity were graded to the level of this well-preserved scar, 13 feet above the present channel. The buried channel seems to have been cut after the meander scar was developed and subsequently to have been filled to that same level. The contemporaneity of the filled channel and the meander must be considered tentative, however, because present-day wind action and wash have disturbed the surface material of the meander, somewhat obscuring the relations with the exposed filled channel.

Recent dunes have formed on the old meander, active blow-outs have reworked the surface layers, and the wind has drifted sand from the meander against the adjacent slopes. The dunes are mostly stabilized by rabbitbrush, saltbush, grass, and weeds.

Along Black Creek, near the south boundary of the Mexican Springs Experiment Station, channeling of the Nakaibito formation similar to that in Mexican Springs Wash is observed. A diagrammatic cross section of one of these buried channels is shown in section A of figure 7. Their depth is nearly as great as that of the present arroyo (12 feet). On Black Creek Wash the channels later were partly filled and the present-day gully has left that surface as a well-marked terrace 12 feet above the present stream bed. The older fill is more high
Though no bones nor artifacts were found in the Gamerco formation, the well-developed caliche layer, the nodules and caliche-filled areas, and the stratigraphic position of the formation appear to make it comparable to the "intermediate alluvium" of Bryan and McCann (1943) at Grants, which is only 60 miles away. The authors have inspected some of the exposures at Grants described by Bryan and McCann as contemporaneous with the Neville formation of the trans-Pecos region (Albritton and Bryan, 1939) and have found that the caliche-cemented gravels of the Neville seem to resemble those at the base of the Gamerco.

Only two potsherds were found in place in the Nakaibito formation. One was of Pueblo I and the other of Pueblo II age. This paucity of datable material makes any correlation tentative, but the fact that the sherds occur in the lower half of the upper part of the Nakaibito near Mexican Springs would indicate that alluviation was continuing as late as A.D. 1200. Inasmuch as the Nakaibito rests on the eroded surface of a fill apparently comparable to Bryan and McCann's "intermediate alluvium" and the Neville formation, the Nakaibito seems to fit into the deposition 2 position of the Bryan-McCann chronology, making it comparable with the Tsegi of Hack (1942), the Calamity formation of the trans-Pecos region, and the and Canyon formation of Judson (1948).

The sparse yet unavoidable indications of a period of stability or erosion during the deposition of the Nakaibito formation are evidence, comparable to that found elsewhere, that deposition 2 consisted of a lower and an upper portion (Hack, 1942; Bryan and McCann, 1943). It would appear, then, that the older fill occurring as an outlier in the Nakaibito of Deer Springs Arroyo and the calichefilled lower part of the fill in upper Mexican Springs Wash correspond to the earlier portion of deposition 2. It therefore seems probable that the main body of the Nakaibito formation which makes up most of the alluvium exposed in the washes of the Gallup area is comparable in age to the upper portion of deposition 2. The present data add to the increasing volume of evidence indicating that the erosional break during deposition 2 was of considerable significance (Judson, 1948).
The period of channel erosion in the Nakaibito formation seems to correspond to the erosion period following the Tsegi formation in the Hopi country and that following the Calamity formation in the trans-Pecos region. Bryan and McCann (1943) tentatively assume that this period of erosion was more or less contemporaneous throughout the localities in the Southwest that have been studied. On the basis of the tentative chronology for the Southwest, deposition 3 is believed to have begun about A.D. 1300; it was probably still continuing when present-day arroyo cutting began in the last quarter of the nineteenth century.

Deposition 3 is represented in the Hopi country by the Naha formation described by Hack (1942), in the trans-Pecos region by the Kokernot formation of Albritton and Bryan (1939), and at the western edge of the High Plains by the Wheatland formation of Judson (1948). The Naha formation represented a considerable volume of material but did not fill to the top the channel that was cut after deposition 2 (the Tsegi formation) was completed. In the trans-Pecos region, deposition 3 not only filled completely the channel cut in the earlier alluvium but covered the whole width of the valley with a thin sheet of alluvial material.

The Wheatland formation of Judson (1948) was a deposit that did not completely fill the channels in which it was laid down. In the Grants area, Bryan and McCann (1943) found deposition 3 to be small in amount of material compared with their deposition 2. These relative volumes are approximately those found in the Gallup region. The channels cut in the Nakaibito formation varied from 10 to 18 feet in depth near Gallup, and at that place the later fill was just sufficient in volume to fill the arroyo approximately to its former level.

In the Mexican Springs area, the erosion that followed deposition 2 cut a channel 19 feet deep. This channel was then filled about halfway to the top (fig. 6). In Deer Springs Wash an indistinct terrace about 3 feet in height can be traced for a considerable distance. It is possible that this terrace marks the depth of cutting during the period between the end of the Nakaibito deposition and the initiation of the present-day arroyos. In Black Creek Wash, only a couple of miles away, the post-Nakaibito erosion cut a channel 17 feet deep, and deposition 3 refilled that channel to a level within 5 feet of the old valley floor.

These observations indicate that the relative sizes of channels cut in the erosion period after deposition 2 varied, not only between widely separated areas as the Hopi country and the trans-Pecos region, but even between closely adjacent localities in the Gallup area.
as is true, also, of the latest epicycle of erosion. At the present
wide differences exist in the size and depth of arroyos, not only
between streams, but along the length of a single channel. Arroyos
in the vicinity of Notam, Utah, reach 45 feet in depth and 30 feet in
width. The channel of the Rio Puerco (del Oriente) varies from
40 to 40 feet in depth and has an average width of 600 to 800 feet
through considerable reaches. Yet there are innumerable valleys
with a drainage area comparable to that of Mexican Springs Wash
above U. S. Highway 666 which have a much smaller arroyo than
contains.

These present-day conditions in no way detract from the possi-
ble that the latest fills observed in various valleys of the South-
est are essentially contemporaneous despite the differences in their
relative size.

The discontinuous channels and the lack of heavy alluviation dur-
ing the period A. D. 1400-1860 possibly indicate an instability of the
top. The climate was not quite humid enough to cause further al-
"mation, nor was it sufficiently arid to cause degradation. On such
stage, postsettlement grazing could play a quick-acting and decisive
role.
